Submitted 25 March 2013; accepted in final form 25 April 2013

Wylie LJ, Kelly J, Bailey SJ, Blackwell JR, Skiba PF, Winyard PG, Jeukendrup AE, Vanhatalo A, Jones AM. Beetroot juice and exercise: pharmacodynamic and dose-response relationships. J Appl Physiol 115: 325–336, 2013. First published May 2, 2013; doi:10.1152/japplphysiol.00372.2013.—Dietary supplementation with beetroot juice (BR) containing approximately 5–8 mmol inorganic nitrate ([NO3]) increases plasma nitrite concentration ([NO2]), reduces blood pressure, and may positively influence the physiological responses to exercise. However, the dose-response relationship between the volume of BR ingested and the physiological effects invoked has not been investigated. In a balanced crossover design, 10 healthy men ingested 70, 140, or 280 ml concentrated BR (containing 4.2, 8.4, and 16.8 mmol NO3, respectively) or no supplement to establish the effects of BR on resting plasma [NO3] and [NO2] over 24 h. Subsequently, on six separate occasions, 10 subjects completed moderate-intensity and severe-intensity cycle exercise tests, 2.5 h postingestion of 70, 140, and 280 ml BR or NO3-depleted BR as placebo (PL). Following acute BR ingestion, plasma [NO2] increased in a dose-dependent manner, with the peak changes occurring at approximately 2–3 h. Compared with PL, 70 ml BR did not alter the physiological responses to exercise. However, 140 and 280 ml BR reduced the steady-state oxygen (O2) uptake during moderate-intensity exercise by 1.7% (P = 0.06) and 3.0% (P < 0.05), whereas time-to-task failure was extended by 14% and 12% (both P < 0.05), respectively, compared with PL. The results indicate that whereas plasma [NO3] and the O2 cost of moderate-intensity exercise are altered dose dependently with NO3-rich BR, there is no additional improvement in exercise tolerance after ingesting BR containing 16.8 compared with 8.4 mmol NO3. These findings have important implications for the use of BR to enhance cardiovascular health and exercise performance in young adults.

nitrate; nitrite; nitric oxide; blood pressure; exercise economy; O2 uptake; exercise tolerance

NITRIC OXIDE (NO) IS A GASEOUS SIGNALING MOLECULE THAT MODULATES HUMAN PHYSIOLOGICAL FUNCTION VIA ITS ROLE IN, FOR EXAMPLE, THE REGULATION OF BLOOD FLOW, NEUROTTRANSMISSION, IMMUNE FUNCTION, GLUCOSE AND CALCIUM HOMEOSTASIS, MUSCLE CONTRACTILITY, AND MITOCHONDRIAL RESPIRATION (9, 36).1 NO IS GENERATED THROUGH THE OXIDATION OF THE AMINO ACID L-ARGININE IN A REACTION CATALYZED BY NO SYNTHASE (NOS), WITH NITRITE (NO2) AND NITRATE (NO3) BEING OXIDATION PRODUCTS OF NO (30). IT IS NOW APPRECIATED THAT UNDER APPROPRIATE PHYSIOLOGICAL CONDITIONS, NO CAN ALSO BE PRODUCED VIA THE REDUCTION OF NO3, A PROCESS THAT MAY BE PARTICULARLY IMPORTANT IN SITUATIONS WHERE OXYGEN (O2) AVAILABILITY IS LOW, AND/OR NOS FUNCTION IS IMPAIRED (12). INTERESTINGLY, ADMINISTRATION OF DIETARY INORGANIC NO3 HAS BEEN SHOWN TO INCREASE PLASMA NO3 CONCENTRATION ([NO3]) AND TO PRODUCE NO-LIKE BIOACTIVITY (19, 23, 39). UP TO 25% OF INGESTED NO3 ENTERS THE ENTEROSALIVARY CIRCULATION AND IS CONCENTRATED IN THE SALIVA, WHEREUPON FACILITATIVE, ANAEROBIC BACTERIA IN THE ORAL CAVITY REDUCE THE NO3 TO NO2 (30). WHEN SWALLOWED INTO THE ACIDIC ENVIRONMENT OF THE STOMACH, SOME OF THE NO2 IS CONVERTED FURTHER INTO NO, WHEREAS THE REMAINDER IS ABSORBED TO INCREASE CIRCULATING PLASMA [NO2]. THIS NO2 MAY BE REDUCED FURTHER TO NO AND OTHER REACTIVE NITROGEN INTERMEDIATES, PARTICULARLY IN TISSUES THAT MAY BE RELATIVELY HYPOXIC, SUCH AS CONTRACTING SKELETAL MUSCLE (30).

We (3, 37) and others (19, 23, 39) have demonstrated that NO3 ingestion, either in the form of NO3 salts or via the consumption of high NO3 vegetable products, such as beetroot juice (BR), reduces resting blood pressure (BP) profoundly and consistently. Consequently, dietary NO3 supplementation has emerged as a potential nutritional agent for the prevention and treatment of hypertension and cardiovascular disease (30). Webb et al. (39) assessed the effects of acute BR consumption (~23 mmol NO3) on plasma [NO3] and BP over 24 h. Plasma [NO2] peaked 3 h postingestion, remained close to peak values until 5 h postingestion, and returned to baseline after 24 h (39). The systolic and diastolic BP and the mean arterial pressure (MAP) were reduced significantly, by ~10, ~8, and ~8 mmHg, respectively, at 2.5–3 h after BR intake. The same research group later reported a dose-dependent increase in plasma [NO3] and [NO2] and reduction in BP following ingestion of potassium NO3 (KNO3) (19). In this study, plasma [NO2] rose by ~1.3-, approximately two-, and approximately fourfold following consumption of 4, 12, and 24 mmol KNO3, respectively. The peak rise in plasma [NO2] was accompanied by significant reductions in both systolic BP (of ~2, ~6, and ~9 mmHg, respectively) and diastolic BP (of ~4, ~4, and ~6 mmHg, respectively). However, since BR contains polyphenols and antioxidants, which can facilitate the synthesis of NO from NO3 in the stomach (30), it is unclear whether BP is similarly impacted when different doses of BR are ingested compared with equivalent doses of NO3 salts. Given the growing interest in dietary NO3 supplementation in the form of BR amongst athletes and the general population, it is important to determine the pharmacokinetic-pharmacodynamic relationship between different volumes of BR consumption and changes in plasma [NO2] and BP to establish an optimal dose for beneficial effects.

Recent investigations suggest that dietary NO3 supplementation has the potential to influence human physiology beyond
the above hemodynamic effects (3, 26). Specifically, we (2, 3, 22) and others (6, 24–26) have demonstrated that 3–6 days of dietary NO₃ supersplementation reduces the O₂ cost of moderate-intensity exercise and may enhance exercise tolerance in healthy, young adults. It appears that these effects are related to NO₂ or NO- mediated enhancements of muscle contractile function (2, 17) and/or mitochondrial efficiency (24) and/or enhanced muscle blood flow, especially to type II fibers (14). Importantly, a reduction of the O₂ cost of exercise (25, 37) and improved exercise performance (21) has also been reported as early as 2.5 h following a single dose of dietary NO₃, which is consistent with the time required for the peak plasma [NO₂⁻] to be attained (39). However, since all exercise-performance studies completed to date with BR have administered approximately 5–8 mmol NO₃, it is unclear whether a dose-response relationship exists between acute NO₃ intake and the physiological responses to exercise. The establishment of the dose-response relationship between NO₃ intake and the physiological responses to exercise and the ascertainment of the optimal NO₃ dose for enhancing exercise performance are important, given the increasing popularity of BR supplementation in both basic research and applied exercise settings.

Therefore, the purpose of the present study was twofold: firstly, to characterize the plasma [NO₃⁻] and [NO₂⁻] pharmacokinetics and the changes in BP after ingestion of three different quantities of NO₃-rich BR; and secondly, to investigate the dose-response relationship between BR/NO₃ intake and the physiological responses to exercise. In two separate experiments, we administered a BR concentrate that enabled a substantial NO₃ load to be ingested quickly and easily. We investigated: 1) the influence of acute NO₃ doses of 4.2, 8.4, and 16.8 mmol consumed in 70, 140, and 280 ml concentrated BR on plasma [NO₃⁻] and [NO₂⁻] and BP over a 24-h period; and 2) the physiological responses to step transitions to moderate- and severe-intensity exercise, 2.5 h post ingestion of the same NO₃ doses. We hypothesized that the effects of dietary inorganic NO₃ on plasma [NO₃⁻] and [NO₂⁻], BP, the O₂ cost of moderate-intensity exercise, and exercise tolerance (assessed as the time-to-task failure) during severe-intensity exercise would be dose dependent.

METHODS

The study was conducted in two phases [study 1 (S₁), pharmacokinetics; and S₂, dose response], with the results generated in S₁ used to inform the experimental design in S₂. There was distinct subject recruitment for each experiment. Ten healthy, recreationally active men volunteered for each experiment [mean ± SD: S₁, age 23 ± 5 yr, height 1.79 ± 0.07 m, body mass (BM) 79 ± 9 kg; S₂, age 22 ± 5 yr, height 1.77 ± 0.05 m, BM 74 ± 8 kg]. None of the subjects in S₁ and S₂ was a tobacco smoker or user of dietary supplements. All subjects recruited for S₂ were fully familiar with laboratory exercise-testing procedures, having participated previously in studies using cycle ergometry in our laboratory. The procedures used in S₁ and S₂ were granted full ethics approval by the Institutional Research Ethics Committee. All subjects gave their written, informed consent to participate after the experimental procedures, associated risks, and potential benefits of participation had been explained in detail.

All subjects in S₁ and S₂ were instructed to keep a food and physical-activity diary in the 24 h preceding their first laboratory visit and to replicate food consumption and physical activity in the 24 h preceding subsequent visits. The subjects were required to arrive at the laboratory in a rested and fully hydrated state, following an overnight fast, and to avoid strenuous activity in the 24 h preceding each testing session. Subjects were instructed to refrain from caffeine and alcohol-containing drinks for 6 and 24 h before each laboratory visit, respectively, and to abstain from using antibacterial mouthwash and chewing gum throughout the study, because these are known to eradicate the oral bacteria that are necessary for the conversion of NO₃ to NO₂ (16).

S₁: Pharmacokinetics and Pharmacodynamics

Procedures. All subjects reported to the laboratory on four separate occasions over a period of 3 wk. Upon arrival at the laboratory, resting BP was measured, and a venous blood sample was obtained for the measurement of plasma [NO₂⁻] and [NO₃⁻]. Subjects then consumed an acute dose of 70, 140, or 280 ml NO₃-rich BR (organic BR containing ~4.2, ~8.4, or ~16.8 mmol NO₂, respectively; Beet It; James White Drinks, Ipswich, UK) or 140 ml water [control (CON)], in addition to a standardized breakfast (72 g porridge oats with 180 ml semiskimmed milk). BP was measured, and a venous blood sample was obtained, 1, 2, 4, 8, 12, and 24 h post ingestion. For each 24-h period of data collection, subjects were provided with a standardized, low NO₃ diet. The quantity and timing of food and drink intake were recorded on visit 1 and replicated in subsequent visits. A washout period of at least 3 days separated the laboratory visits.

Measurements. The BP of the brachial artery was measured using an automated sphygmomanometer (Dinamap Pro; GE Medical Systems, Tampa, FL), with the subjects in a seated position. After arrival at the laboratory and following 10 min of rest in an isolated room, four measurements were recorded, and the mean of the final three measurements was used for data analysis.

Venous blood samples were drawn into lithium-heparin tubes (7.5 ml Monovette lithium heparin; Sarstedt, Leicester, UK). Samples were centrifuged at 4,000 rpm and 4°C for 7 min, within 1 min of collection. Plasma was subsequently extracted and immediately frozen at −80°C for later analysis of [NO₂⁻] and [NO₃⁻].

All glassware, utensils, and surfaces were rinsed with deionized water to remove residual [NO₃⁻] and [NO₂⁻] before blood analyses. The [NO₃⁻] of the undiluted (nondigested protein) plasma was determined by its reduction to NO in the presence of glacial acetic acid and 4% (w/v) aqueous sodium iodide. The spectral emission of electronically excited nitrogen dioxide product, from the NO reaction with ozone, was detected by a thermoelectrically cooled, red-sensitive photomultiplier tube, housed in a Sievers gas-phase chemiluminescence NO analyzer (NOA; Sievers NOA 280i: Analytix, Durham, UK). The [NO₂⁻] was determined by plotting signal (mV) area against a calibration plot of 100 nM–1 μM sodium NO₂. Before determination of [NO₃⁻], samples were deproteinized using zinc sulfate (ZnSO₄)/sodium hydroxide (NaOH) precipitation. Aqueous ZnSO₄ [400 μl 10% (w/v)] and 400 μl 0.5 M NaOH were added to 200 μl of sample and vortexed for 30 s before being left to stand at room temperature for 15 min. Thereafter, samples were centrifuged at 4,000 rpm for 5 min, and the supernatant was removed for subsequent analysis. The [NO₃⁻] of the deproteinized plasma sample was determined by its reduction to NO in the presence of 0.8% (w/v) vanadium trichloride in 1 M HCl. The production of NO was detected using the chemiluminescence NOA, as described above.

To determine more precisely the time-to-peak plasma [NO₂⁻] following NO₃ ingestion, a one-compartment model with first-order absorption and elimination kinetics was used, as described in the following equation

\[
Y = \exp(-Ke \times X/(Ke/Ka)) - \exp(-Ke \times X)/(Ke/Ka - 1)
\]

where Y represents fraction absorbed; X represents time; and, Ka and Ke represent the first-order absorption and elimination rate constants, respectively.

Statistical analysis. Two-way repeated-measures ANOVA was used to assess the difference across conditions (4.2, 8.4, and 16.8

J Appl Physiol • doi:10.1152/japplphysiol.00372.2013 • www.jappl.org
mmol NO₃⁻ and CON) and across time (0, 1, 2, 4, 8, 12, and 24 h) for plasma [NO₂⁻] and [NO₃⁻] and BP. Significant main or interaction effects were analyzed further using simple contrasts. One-way repeated-measures ANOVA was used to assess the differences in time-to-peak plasma [NO₂⁻]. Relationships between plasma [NO₂⁻] and BP were analyzed using Pearson product moment correlation coefficients. Statistical significance was accepted at \( P < 0.05 \). Results are presented as mean ± SD unless stated otherwise.

**S₂: Dose Response**

**Protocol.** Subjects were required to report to the laboratory on seven separate occasions, over a 4- to 5-wk period. During the first visit to the laboratory, subjects completed a ramp incremental exercise test for determination of peak \( \text{O}_2 \) uptake (\( \text{VO}_2 \text{peak} \)) and gas-exchange threshold (GET). All tests were performed on an electronically braked cycle ergometer (Lode Excalibur Sport, Groningen, The Netherlands). Initially, each subject completed 3 min of “unloaded” baseline cycling; then, the work rate was increased by 30 W/min until the subject was unable to continue. The subjects cycled at a self-selected pedal rate (70–90 rpm), and this pedal rate along with the saddle and handlebar height and configuration were recorded and reproduced in subsequent tests. The breath-by-breath pulmonary gas-exchange data were collected continuously during the incremental tests and averaged over consecutive 10-s periods. \( \text{VO}_2 \text{peak} \) was taken as the highest 30-s average. The final 30 s of exercise was dermined as described previously (3, 37). The work rates that would require 80% of the GET (moderate-intensity exercise) and 75% of the difference between the power output at GET and \( \text{VO}_2 \text{peak} \) plus the power output at GET, i.e., severe-intensity exercise (\( \Delta \)) were subsequently calculated.

On test days, subjects arrived at the laboratory at ~8 AM. A venous blood sample was drawn for measurement of plasma [NO₂⁻] and NO₃⁻. Subjects then ingested 70, 140, or 280 ml NO₃⁻-rich BR (containing 4.2, 8.4, or 16.8 mmol NO₃⁻, respectively; Beet It) or 70, 140, or 280 ml NO₃⁻-depleted BR as a placebo (PL70, PL140, or PL280; containing ~0.04, ~0.08, or ~0.12 mmol NO₃⁻; Beet It). All BR and PL doses were administered using a randomized, double-blind crossover design. Subjects were asked to consume the beverage within a 5-min period. After dosing, subjects were served a standardized breakfast (72 g porridge with 180 ml semiskimmed milk). A washout period of at least 72 h separated each visit.

After ingestion of the beverage, subjects were given a period of 2.5 h, during which they were allowed to leave the laboratory but were asked to refrain from strenuous physical activity. Subjects were also asked to fast during this time, although water was permitted ad libitum. Following this 2.5-h period, a second venous blood sample was drawn for measurement of plasma [NO₂⁻] and NO₃⁻. Subjects then ingested 70, 140, or 280 ml NO₃⁻-rich BR (containing 4.2, 8.4, or 16.8 mmol NO₃⁻, respectively; Beet It) or 70, 140, or 280 ml NO₃⁻-depleted BR as a placebo (PL70, PL140, or PL280; containing ~0.04, ~0.08, or ~0.12 mmol NO₃⁻; Beet It). All BR and PL doses were administered using a randomized, double-blind crossover design. Subjects were asked to consume the beverage within a 5-min period. After dosing, subjects were served a standardized breakfast (72 g porridge with 180 ml semiskimmed milk). A washout period of at least 72 h separated each visit.

These analyzers were calibrated before each test with gases of known concentration, and the turbine volume transducer was calibrated using a 3-liter syringe (Hans Rudolph, Kansas City, MO). The volume and concentration signals were time aligned by accounting for the delay in capillary gas transit and analyze rise time relative to volume signal. \( \text{O}_2 \) uptake, \( \text{CO}_2 \) output, and minute ventilation were calculated using a standard formula and displayed breath by breath. Heart rate (HR) was measured using short-range radiotelemetry (model RS400; Polar Electro Oy, Kempele, Finland).

Capillary blood samples were collected from the fingertip into a capillary tube during the baseline, preceding each step transition in work rate; during the final 30 s of each moderate-intensity exercise bout; and following exhaustion in the severe-intensity exercise bout. These samples were analyzed immediately to determine blood lactate concentration ([lactate]; model YSI 1500; Yellow Springs Instrument, Yellow Springs, OH). Venous blood samples were treated and analyzed as described in S₁.

The breath-by-breath data from each exercise test were linearly interpolated to provide second-by-second values, and the two identical, moderate-intensity repetitions performed on each visit were time aligned to the start of exercise and ensemble averaged. Baseline \( \text{VO}_2 \), \( \text{VCO}_2 \), and RER were defined as the mean values measured over the final 30 s of exercise. The amplitude of the \( \text{VO}_2 \) response was calculated by subtracting \( \text{VO}_2 \text{baseline} \) from \( \text{VO}_2 \) at the end of exercise. Subsequently, the functional gain of the entire response was calculated by dividing the \( \text{VO}_2 \) amplitude by the change (\( \Delta \)) in work rate. The amplitude of the \( \text{VO}_2 \) slow component during the severe-intensity exercise bout was estimated by subtracting the mean \( \text{VO}_2 \) at 2 min from the mean \( \text{VO}_2 \) at 6 min.

**Statistical analysis.** Two-way repeated-measures ANOVA was used to assess the difference in pulmonary gas-exchange variables, \( \text{VO}_2 \), \( \text{VCO}_2 \), and HR across dose (70, 140, and 280 ml) and treatment (PL and BR). Differences in pre- and postplasma [NO₂⁻] and [NO₃⁻] were assessed separately in PL and BR, across dose and time (pre and post) using two-way repeated-measures ANOVAs. Significant main and interaction effects were analyzed further using simple contrasts. Statistical significance was accepted at \( P < 0.05 \). Results are presented as mean ± SD unless stated otherwise.

**RESULTS**

Ingestion of BR was tolerated well by all subjects in S₁ and S₂. Subjects did, however, report beeturia (red urine) and red stools, consistent with previous studies (3, 39). The absolute NO₃⁻ doses used in S₁ and S₂ (4.2, 8.4, and 16.8 mmol) were equivalent to ~0.05 ± 0.01 (range: 0.05–0.07), ~0.11 ± 0.01 (range: 0.09–0.13), and ~0.22 ± 0.03 mmol (range: 0.19–0.26) NO₃⁻/kg BM, respectively.

**S₁: Pharmacokinetics and Pharmacodynamics**

The effects of different volumes of BR (and therefore, different amounts of ingested NO₃⁻) on plasma [NO₂⁻] and [NO₃⁻] are presented in Fig. 1. There were significant main effects by dose and time and an interaction effect for both plasma [NO₂⁻] and [NO₃⁻]. All plasma [NO₂⁻] and [NO₃⁻] were assessed separately in PL and BR, across dose and time (pre and post) using two-way repeated-measures ANOVAs. Significant main and interaction effects were analyzed further using simple contrasts. Statistical significance was accepted at \( P < 0.05 \). Results are presented as mean ± SD unless stated otherwise.

The inspirated and expired gas volume and gas concentration signals were sampled continuously at 100 Hz—the latter using paramagnetic (\( \text{O}_2 \)) and infrared [carbon dioxide (\( \text{CO}_2 \))] analyzers (Oxycon Pro; Jaeger GmbH) via a capillary line connected to the mouthpiece.
administration of 16.8 mmol NO3− relative to both 8.4 mmol (146 min; range: 63–192 min; P < 0.05). ANOVA analyses revealed significant dose-dependent increases in plasma [NO3−] following BR supplementation (P < 0.05). The peak elevation above baseline in plasma [NO3−] occurred 2 h postadministration of 4.2 (220 ± 104 nM) and 8.4 mmol NO3− (374 ± 173 nM) and 4 h postadministration of 16.8 mmol NO3− (653 ± 356 nM; Fig. 1B; all P < 0.05). Kinetic analyses revealed that plasma [NO3−] peaked significantly later (198 ± 64 min; range: 130–367 min) following ingestion of 16.8 mmol relative to both 8.4 mmol (146 ± 38 min; range: 77 ± 213 min; P < 0.05) and 4.2 mmol BR (106 ± 39 min; range: 63–192 min; P < 0.05). Peak plasma [NO3−], following ingestion of 8.4 mmol, tended to occur later compared with 4.2 mmol (P = 0.06). Plasma [NO3−] remained elevated above baseline and CON at 1, 2, 4, and 8 h after administration of 4.2, 8.4, and 16.8 mmol NO3− (all P < 0.05). At 12 h, plasma [NO3−] remained elevated above baseline and 4.2 mmol BR following ingestion of 8.4 and 16.8 mmol NO3− (all P < 0.05). In addition, plasma [NO3−] remained elevated at 24 h following administration of 16.8 mmol NO3− compared with all other doses (P < 0.05).

The effects of different volumes of BR (and therefore, different amounts of ingested NO3−) on systolic and diastolic BP and MAP are presented in Fig. 2. The changes in systolic BP across all conditions are presented in Fig. 2A. There were significant main effects by dose and time and an interaction effect on systolic BP (all P < 0.05). Systolic BP at baseline, before administration of any beverage, was lower (P < 0.05) in the 16.8-mmol NO3− condition (118 ± 5 mmHg) relative to CON (121 ± 5 mmHg) but not relative to 4.2 (119 ± 6 mmHg) and 8.4 mmol NO3− (120 ± 6 mmHg). Compared with baseline, systolic BP was lowered significantly following ingestion of 4.2, 8.4, and 16.8 mmol NO3− (all P < 0.05). The peak reduction in systolic BP occurred 4 h postadministration of 4.2 (5 ± 5 mmHg), 8.4 (10 ± 5 mmHg), and 16.8 mmol NO3− (9 ± 4 mmHg), respectively, relative to baseline (all P < 0.05). Systolic BP was reduced relative to baseline, CON, and 4.2 mmol NO3−, at 2, 4, and 8 h postadministration of 8.4 mmol and 16.8 mmol NO3− (all P < 0.05). There were no differences in systolic BP between 8.4 and 16.8 mmol NO3− at any time point (P > 0.05). At 24 h, systolic BP remained significantly lower (by 5 ± 5 mmHg) than baseline, following consumption of 16.8 mmol NO3− (P < 0.05). In contrast, systolic BP was not significantly different than CON or baseline at 24 h postad-
administration of 4.2 and 8.4 mmol NO$_3^-$ (P > 0.05). Overall, the mean systolic BP across 24 h, relative to CON, was lowered dose dependently by ~3, ~4, and ~6 mmHg after administration of 4.2, 8.4, and 16.8 mmol NO$_3^-$, respectively (all P < 0.05). The change in systolic BP was correlated with the change in plasma [NO$_3^-$] (r = −0.27; P < 0.05) and the change in plasma [NO$_2^-$] (r = −0.37; P < 0.05). The peak reduction in systolic BP was not correlated with the baseline systolic BP.

The changes in diastolic BP following the ingestion of different doses of NO$_3^-$-rich BR are presented in Fig. 2B. There was a significant interaction effect (dose × time) on diastolic BP (P < 0.05). Diastolic BP at baseline was not significantly different among conditions (CON: 67 ± 5; 4.2 mmol: 68 ± 4; 8.4 mmol: 68 ± 6; 16.8 mmol: 67 ± 6 mmHg; P > 0.05). Follow-up tests revealed that ingestion of 8.4 and 16.8 but not 4.2 mmol NO$_3^-$ reduced diastolic BP significantly, relative to baseline and CON (all P < 0.05). The peak reduction in diastolic BP from baseline occurred at 4 h postadministration of 8.4 mmol NO$_3^-$ (3 ± 3 mmHg) and 2 h postadministration of 16.8 mmol NO$_3^-$ (4 ± 4 mmHg; both P < 0.05) relative to baseline (both P > 0.05) and returned to near-baseline values by 24 h (P > 0.05). There were no differences in diastolic BP between 8.4 and 16.8 mmol NO$_3^-$ at any time point (P > 0.05). The change in diastolic BP was correlated with the change in plasma [NO$_3^-$] (r = −0.35; P < 0.05) and the change in plasma [NO$_2^-$] (r = −0.39; P < 0.05). Moreover, the peak change in diastolic BP was correlated with the baseline diastolic BP (r = −0.49; P < 0.05).

The changes in MAP following the ingestion of different doses of NO$_3^-$-rich BR are presented in Fig. 2C. There were significant main effects by dose and time and an interaction effect on MAP (all P < 0.05). At baseline, before the ingestion of any beverage, MAP was not significantly different among conditions (CON: 85 ± 4; 4.2 mmol: 85 ± 4; 8.4 mmol: 85 ± 5; 16.8 mmol: 84 ± 5 mmHg; P > 0.05). MAP was significantly lower following ingestion of 4.2, 8.4, and 16.8 mmol NO$_3^-$ relative to baseline and CON (all P < 0.05). Following ingestion of 4.2 mmol NO$_3^-$, the peak reduction (2 ± 2 mmHg) in MAP occurred at 1 h, and MAP remained reduced by ~2 mmHg at 2 h relative to baseline (P < 0.05). In contrast, the peak reduction in MAP (5 ± 3 mmHg) occurred 4 h postadministration of 8.4 and 16.8 mmol NO$_3^-$ relative to baseline (P < 0.05). MAP was not different between 8.4 and 16.8 mmol NO$_3^-$ at any time point (P > 0.05). Overall, the mean MAP across 24 h, relative to CON, was reduced dose dependently by ~1, ~2, and ~4 mmHg after administration of 4.2, 8.4, and 16.8 mmol NO$_3^-$, respectively (all P < 0.05). The change in MAP was correlated significantly with the change in plasma [NO$_3^-$] (r = −0.35; P < 0.05) and the change in plasma [NO$_2^-$] (r = −0.41; P < 0.05).

### S2: Dose Response

**Plasma [NO$_3^-$] and [NO$_2^-$].** The group mean plasma [NO$_3^-$] and [NO$_2^-$] responses in the BR and PL conditions are illustrated in Fig. 3, A and B, respectively. Presupplementation plasma [NO$_3^-$] was not significantly different between conditions (P > 0.05), and no significant change in plasma [NO$_3^-$] was observed following PL supplementation (P > 0.05). ANOVA analyses revealed a significant dose-dependent increase in plasma [NO$_3^-$] at 2.5 h following BR supplementation (P < 0.05). An elevation in plasma [NO$_3^-$] above baseline was apparent following 4.2 (130 ± 17 μM; P < 0.05), 8.4 (282 ± 54 μM; P < 0.05), and 16.8 mmol NO$_3^-$ (580 ± 89 μM; P < 0.05). Presupplementation plasma [NO$_2^-$] was not significantly different among conditions (P > 0.05), and no significant change in plasma [NO$_2^-$] was observed following PL supplementation (P > 0.05). ANOVA analyses revealed a significant dose-dependent increase in plasma [NO$_2^-$] at 2.5 h following BR supplementation (P < 0.05). Following administration of 4.2, 8.4, and 16.8 mmol NO$_3^-$, plasma [NO$_2^-$] was elevated above baseline by 150 ± 73 nM, 291 ± 145 nM, and 425 ± 225 nM, respectively (all P < 0.05). Plasma [NO$_2^-$] was significantly greater after ingestion of 16.8 mmol compared with 4.2 mmol NO$_3^-$ (P < 0.05) and tended to be greater compared with 8.4 mmol NO$_3^-$ (P = 0.06). Plasma [NO$_2^-$] was

B

![Graph B](image)

There was no significant difference in end-exercise $\dot{V_O}_2$ compared with ingestion of 70 ml of supplement relative to 70 and 140 ml of supplement (P > 0.05).

Baseline and end-exercise RER were affected by dose (P < 0.05 for both) but not condition (P > 0.05). The follow-up tests indicated that RER increased as the volume of supplement ingested increased (P < 0.05; Table 1). Specifically, RER at baseline was increased by ~5% and ~4% following consumption of 280 ml of supplement relative to 70 and 140 ml, respectively (P < 0.05 for both). Although there was no significant interaction effect or main effect by condition, baseline RER tended to be higher (by ~3%) following administration of 16.8 mmol NO3 compared with the respective PL (P = 0.08). End-exercise RER was increased significantly by ~4% and ~3%, following consumption of 280 ml compared with 70 and 140 ml of supplement, respectively (P < 0.05 for both). In addition, the ingestion of 140 ml increased end-exercise RER compared with ingestion of 70 ml of supplement (P < 0.05). The baseline, end-exercise, and change in blood [lactate] and HR were not altered significantly by dose or condition (Table 2; P > 0.05).

Severe-intensity exercise. The pulmonary gas exchange and ventilatory responses to severe-intensity exercise across all doses and conditions are summarized in Table 1. In contrast to the effects observed for moderate-intensity exercise, the $\dot{V_O}_2$ and $\dot{V}_{CO}_2$ measured at baseline and at task failure were not altered by dose or treatment (all P > 0.05). Moreover, neither the dose nor the treatment altered the $\dot{V_O}_2$ slow component amplitude (P > 0.05 for both). There was a trend toward significant main effects by dose (P = 0.09) and treatment (P = 0.08) but no interaction effect on RER at baseline (P > 0.05). Follow-up tests revealed that there was a trend toward significant increases in RER at baseline by ~4% and ~3% following consumption of 280 ml of supplement compared with the consumption of 70 (P = 0.06) or 140 ml (P = 0.08) of supplement, respectively. RER, at task failure, was not altered by dose or treatment (P > 0.05). The baseline, end-exercise, and change in blood [lactate] and HR were not altered significantly by dose or condition (Table 2; P > 0.05).

There was a significant main effect by condition (P < 0.05) but not dose (P > 0.05) on time-to-task failure (Table 1 and

As expected, the rise in plasma [NO$_3^-$] was smaller compared with plasma [NO$_3^-$], with peak increases of ~2.5-fold, approximately fourfold, and approximately eightfold, respectively. The delayed peak increases in plasma [NO$_3^-$] compared with plasma [NO$_3^-$] reflect the importance of the enterosalivary circulation and subsequent reduction of NO$_3^-$ to NO$_2^-$ by lingual bacteria (16, 39). These pharmacokinetic responses to BR supplementation are consistent with those reported previously following acute ingestion of KNO$_3$ (19). Together, these data suggest that the pharmacokinetics of plasma [NO$_3^-$] and [NO$_2^-$] are dose dependent when NO$_3^-$ is administered, either as NO$_3^-$ salt or in the form of a natural vegetable supplement.

Ingestion of concentrated BR dose dependently lowered systolic BP and MAP up to an intake of 8.4 mmol NO$_3^-$. More specifically, acute ingestion of 4.2, 8.4, and 16.8 mmol inorganic NO$_3^-$, administered in the form of BR, resulted in peak reductions of systolic BP of ~5, ~10, and ~9 mmHg and peak reductions of MAP of ~2, ~5, and ~5 mmHg, respectively. Moreover, BR ingestion resulted in a similar “threshold” effect on diastolic BP, with peak reductions of ~3 and ~4 mmHg following administration of 8.4 and 16.8 mmol NO$_3^-$; however, ingestion of 4.2 mmol NO$_3^-$ did not reduce diastolic BP significantly. These reductions in BP are similar to those reported by Kapil et al. (19) following acute administration of KNO$_3$, except that Kapil et al. (19) reported a dose-dependent reduction in BP up to 24 mmol KNO$_3$. The reason for this discrepancy between studies is unclear. Interestingly, compared with Kapil et al. (19), who reported 6 mmHg and 9 mmHg reductions in systolic BP following the consumption of 12 mmol and 24 mmol KNO$_3$, respectively, we observed larger reductions in BP following the consumption of BR (e.g., a peak reduction of 10 mmHg in systolic BP with 8.4 mmol NO$_3^-$ contained in 140 ml BR). It is possible that this apparent greater potency of BR compared with NO$_3^-$ salt in reducing BP is related to the polyphenols and other antioxidants present in BR, which may facilitate a more efficient conversion of NO$_3^-$ to NO$_2^-$ (30). Interestingly, although the peak reduction in BP was not significantly different between 8.4 and 16.8 mmol NO$_3^-$, the mean reduction in BP over 24 h was dose dependent, with MAP, for example, reduced by 1.2, and 4 mmHg following administration of 4.2, 8.4, and 16.8 mmol NO$_3^-$, respectively.

The results of the present study suggest that BR (and presumably other NO$_3^-$-rich vegetable) consumption can provide a natural approach to maintaining or improving BP and

vascular health in young adults. The reductions in BP, evident in the present study, are noteworthy. For example, it has been suggested that lowering systolic BP by 10 mmHg may reduce the risk of ischemic heart disease by ~25% and the risk of stroke by ~35% (27–29, 31). The beneficial hemodynamic effects of NO3 supplementation are thought to be due to the reduction of NO3 to NO2 and then to NO within the blood vessel (13), resulting in arterial dilatation and a reduced peripheral resistance (39). However, it is possible that NO2 itself may also exert a direct effect on the vascular system, independent of NO formation (1). There are several advantages to using inorganic rather than organic NO3 for the prevention or treatment of hypertension (33). These include a slow and controlled increase in plasma [NO2\textsuperscript{-}] following inorganic NO3 intake (due to NO3\textsuperscript{-} uptake into the enterosalivary circulation) compared with the more abrupt changes in plasma [NO3\textsuperscript{-}] (perhaps to toxic levels) and BP, which can occur with organic NO3 administration (33). Moreover, unlike the chronic administration of organic NO3, inorganic NO3 does not appear to lead to the development of tolerance (37) and endothelial dysfunction (33).

**S2: Dose Response**

The results of S2 confirm that concentrated BR consumption causes a dose-dependent increase in plasma [NO3\textsuperscript{-}] by 334%, 778%, and 1,556% and plasma [NO2\textsuperscript{-}] by 121%, 218%, and 338%, 2.5 h postingestion of 4.2, 8.4, and 16.8 mmol NO3\textsuperscript{-}, respectively. The magnitude of the increase in plasma [NO2\textsuperscript{-}] following consumption of 8.4 and 16.8 mmol NO3\textsuperscript{-} in the present study was much larger than the approximate 15–150% rise in plasma [NO3\textsuperscript{-}], reported previously, following acute (approximately 4–6 mmol) (5, 21, 25, 37) and chronic (approximately 5–6 mmol/day) (2, 3, 22, 26, 37) dietary NO3\textsuperscript{-} supplementation. This finding is likely a consequence of the relatively higher NO3\textsuperscript{-} doses (8.4 and 16.8 mmol NO3\textsuperscript{-}) administered in the present study. Interestingly, the group mean plasma [NO3\textsuperscript{-}] and [NO2\textsuperscript{-}] reported in S2 are somewhat lower than those reported at 2–4 h postingestion of 5.2 mmol NO3\textsuperscript{-} (~0.07 mmol/kg BM) in the form of nonconcentrated BR (37) but is smaller than the 6% reduction reported 1 h postingestion of 0.033 mmol/kg BM sodium nitrate (25). In contrast to acute ingestion, longer-term BR supplementation (3–6 days at an approximately 5–7 mmol NO3\textsuperscript{-}/day) resulted in an approximate 5–7% reduction in steady-state VO2 during moderate-intensity cycling (3, 26) and running (22).

Previous studies have indicated that the lowering of submaximal exercise VO2, following dietary NO3\textsuperscript{-} supplementation, may result from improved mitochondrial efficiency (25) and/or a reduction in the ATP cost of muscle force production (4). Alterations in protein expression have been proposed as the mechanistic basis for these effects (17, 24); however, it is unlikely that these alterations occur quickly enough to explain the effects observed so far (1–2.5 h after NO3\textsuperscript{-} ingestion (25, 37). Alternatively, NO may acutely and reversibly impact protein function through post-translational protein modifications. For instance, S-nitrosation of adenine nucleotide translocase or other mitochondrial or calcium-handling proteins (35) may contribute to the acute reduction in O2 cost of exercise following BR ingestion. The mechanistic basis for the acute changes in the O2 cost of exercise following BR ingestion warrants further investigation.

An interesting observation was the dose-dependent increase in baseline and end-exercise VCO2, irrespective of condition (i.e., PL or BR). This small but significant rise in VCO2 led to a dose-dependent increase in RER that was more pronounced during baseline cycling compared with the exercising steady-state. An elevation in RER is indicative of a shift in substrate use toward a relatively greater reliance on carbohydrate and is likely due to the sugar content of the concentrated BR and PL beverages (~16 g/70 ml).

**Dose Response: Severe-Intensity Exercise**

A novel finding of the present study was that 8.4 and 16.8 mmol NO3\textsuperscript{-}, but not 4.2 mmol NO3\textsuperscript{-}, administered acutely in the form of concentrated BR, significantly improved the time-to-task failure by 14% and 12%, respectively, during severe-intensity exercise. These findings are similar to the 14–16% improvement in exercise tolerance reported previously following 5–6 days of BR supplementation at a lower dose (5–6 mmol NO3\textsuperscript{-}) (3, 22). Although the mechanism(s) responsible for the ergogenic potential of NO3\textsuperscript{-} supplementation remain uncertain, they are believed to be mediated via a biochemical reduction of ingested NO3\textsuperscript{-} to biologically active NO2\textsuperscript{-} and NO (4).

NO has been linked to the efficiency of aerobic respiration (9) and the regulation of muscle contraction (35). Indeed, both more efficient mitochondrial oxidative phosphorylation, via a reduced proton leak across the inner mitochondrial membrane.
and a reduced ATP and phosphocreatine cost of muscle force production (2, 15), has been reported following dietary NO$_3^-$ supplementation. In addition, recent evidence suggests that BR supplementation results in a marked increase in muscle blood flow during exercise in rats, with the blood flow preferentially distributed to muscle groups that principally contain type II fibers, which are recruited during severe-intensity exercise (14). Furthermore, NO$_3^-$ supplementation has been shown to increase muscle force production in mice via modulation of intracellular calcium ion (Ca$^{2+}$) handling in fast-twitch fibers (17). It is possible that these mechanisms operate simultaneously and/or synergistically, resulting in enhanced exercise tolerance. It is, however, important to note that the studies that demonstrated effects of NO$_3^-$ supplementation on muscle metabolic and vascular control mechanisms (2, 14, 17, 24) used chronic, rather than acute, NO$_3^-$ supplementation protocols. On the other hand, Cosby et al. (10) reported acutely increased blood flow to exercising forearm muscle following infusion of NO$_2$ into the brachial artery. It is possible that the improved time-to-task failure that we observed with 8.4 and 16.8 mmol NO$_3^-$ was related to improved blood flow to muscle or to a NO-mediated enhancement of local matching of O$_2$ delivery to metabolic rate. This would be consistent with reports that BR supplementation results in a preferential distribution of blood flow to type II fibers (14) and improves oxidative function in hypoxic muscle (38). The lack of a further improvement in time-to-task failure with 16.8 mmol compared to 8.4 mmol NO$_3^-$ mirrors the lack of an additional effect of consuming the higher NO$_3^-$ dose on the peak reduction in BP that we observed in S1, suggesting that the acute effects of BR ingestion on exercise tolerance may be related, at least in part, to effects on the vasculature. Further studies are needed to establish which mechanisms may be responsible for the ergogenic potential of NO$_3^-$, at least at high doses, as early as 2.5 h after ingestion of BR.

The results of the present study indicate a dose-dependent effect of BR supplementation on exercise tolerance up to 8.4 mmol, with no further benefit (indeed a small reduction in exercise tolerance compared with 8.4 mmol) following ingestion of 16.8 mmol NO$_3^-$. A possible explanation for this threshold might be a NO-dependent reduction in skeletal muscle force via modulation of excitation-contraction coupling. It has been reported that the opening of the Ca$^{2+}$ release channels of the sarcoplasmic reticulum (SR) is inhibited by NO (32, 35) and highly related to NO availability (35). In addition, Ca$^{2+}$ transport (35), SR Ca$^{2+}$-ATPase activity (18), and cytochrome c-oxidase inhibition (9) may be influenced by NO and contribute to a dose-dependent modulation of excitation-contraction coupling. Therefore, whereas an increase in NO bioavailability may result in a more efficient mitochondrial function (24) and changes to type II fiber contractility (17) and blood flow (14), it is possible that these positive effects may be offset by impairments of mitochondrial or contractile function at higher NO levels that might promote nitrative stress. These suggestions are naturally speculative and await further investigation.

The improvements in time-to-task failure during severe-intensity exercise, following ingestion of 8.4 and 16.8 mmol NO$_3^-$ in the present study, were evident without any significant changes in the VO$_2$ response to exercise. Neither the amplitude of the VO$_2$ slow component nor the end-exercise VO$_2$ was influenced by acute ingestion of up to 16.8 mmol NO$_3^-$. This finding is consistent with some (20) but not all previous reports (3, 22). For example, Bailey et al. (3) reported that 3 days of BR supplementation reduced the VO$_2$ slow-component amplitude by 23% and improved exercise tolerance by ~16%. In contrast, Kelly et al. (20) reported that 3 days of BR supplementation improved exercise tolerance at three different severe intensities by 12–17%, without any accompanying changes in the VO$_2$ response. We found no difference in end-exercise VO$_2$ between BR and PL at any dose. In the severe exercise-intensity domain, the VO$_2$ at the point of volitional exhaustion would be expected to equal the maximum VO$_2$ (VO$_2$ max) (11). Our results are therefore consistent with some (3, 37) but not all (5, 25) previous studies that indicate that NO$_3^-$ supplementation does not reduce VO$_2$ max. Interestingly, there was a disconnect between the effects of BR on steady-state VO$_2$ during moderate-intensity exercise (where the greatest reduction occurred at the highest dose of NO$_3^-$) and the effects of BR on exercise tolerance (where the increased time-to-task failure was similar with 8.4 and 16.8 mmol NO$_3^-$). Collectively, these results appear to indicate that the effects of BR on severe-intensity exercise performance may be independent from the effects of BR on the O$_2$ cost of submaximal exercise.

It should be noted that while an approximate 12–14% extension of time-to-task failure during severe-intensity, constant work-rate exercise, following acute BR ingestion, may appear impressive, this is likely to translate into no more than a 1–2% reduction in the time to complete a given distance, for example, during a short endurance time-trial (TT) event (34). This is similar to the magnitude of improvement in performance reported previously for 4 km and 16.1 km TT after acute BR ingestion (21) and for 10 km TT following 6 days of BR supplementation (6). A 1% improvement in performance is highly meaningful in elite sport. For example, it could improve 1,500-m running performance by ~2 s or 3,000-m running performance by approximately 4–5 s in international standard athletes. It remains unclear, however, whether elite athletes may confer a performance benefit from NO$_3^-$ supplementation. Several studies now indicate that at least when NO$_3^-$ is ingested acutely, TT performance is not enhanced in highly trained endurance athletes (7, 8, 40). This may be related to factors such as greater NOS activity, better muscle oxygenation and mitochondrial efficiency, and a lower fraction of type II fibers in the muscles of highly endurance trained compared with moderately trained subjects (40). It is possible that the dose-response relationship between NO$_3^-$ ingestion and changes in exercise performance are different in elite compared with sub-elite subjects, such that larger NO$_3^-$ doses and/or longer supplementation periods may be required to elicit improved exercise performance. The significant correlation between the change in plasma [NO$_3^-$] and the change in time-to-task failure indicates that the dietary NO$_3^-$ intervention must be sufficient to increase plasma [NO$_2^-$] if performance is to be improved. In this regard, an important consideration may be the timing of supplementation relative to the start of exercise. The present study shows that on average, plasma [NO$_3^-$] takes longer to peak when larger doses of NO$_3^-$ are imbibed. However, there are appreciable interindividual differences in the speed with which ingested NO$_3^-$ is reduced to NO$_2^-$, which may preclude any more specific advice other than to consume NO$_3^-$ some 2–3 h before the start of exercise.
It has been suggested previously that there may be "responders" and nonresponders to dietary NO3 supplementation (40), and there was evidence of this in the present study. Interestingly, the number of nonresponders (in terms of exercise capacity) decreased as the dose ingested increased. For example, there were three nonresponders in the 4.2-mmol condition, two in the 8.4-mmol condition, and one in the 16.8-mmol condition. Two of the subjects who did not respond at the lowest dose did respond to the larger doses, and one subject who did not respond following administration of 4.2 or 8.4 mmol did respond to the 16.8-mmol dose. This suggests that some individuals will require a larger acute dose than others to elicit any positive effects on exercise capacity from dietary NO3 ingestion. Unlike in our previous study (40), the increase in plasma [NO3] from baseline to pre-exercise for the nonresponders was not smaller than that measured in other subjects who did respond, and the nonresponders did not have particularly high baseline plasma [NO3]. In a recent study, we found that the subjects who demonstrated improved high-intensity, intermittent exercise performance following dietary NO3 supplementation were those whose plasma [NO3] fell significantly during exercise (41). We did not measure plasma [NO2] postexercise in the present study. The explanation for the existence of responders and nonresponders to dietary NO3 supplementation is presently obscure.

In conclusion, dietary supplementation with NO3-rich BR dose dependently increased plasma [NO3] and [NO2] up to 16.8 mmol NO3 and caused peak reductions in systolic BP and MAP dose dependently, up to 8.4 mmol NO3. These results suggest that the consumption of high NO3 foodstuffs may be an effective strategy for maintaining and perhaps enhancing vascular health in young adults. The present study also demonstrated that the O2 cost of moderate-intensity exercise is reduced dose dependently, up to 16.8 mmol NO3. Supplementation with 4.2 mmol NO3 did not enhance time-to-task failure relative to PL; however, supplementation with 8.4 mmol NO3 significantly improved time-to-task failure relative to PL, with no further improvement evident following supplementation with 16.8 mmol NO3. Although the mechanistic bases for the reduction in the O2 cost of submaximal exercise and enhancements in exercise tolerance following acute dietary BR remain unclear, these results provide important, practical information that may underpin the potential use of BR/NO3 supplementation for improving cardiovascular health in the general population and for enhancing exercise performance in athletes.
